Abstract

Are estrous mate preference shifts robust? This question is the subject of controversy within human evolutionary sciences. For nearly two decades, mate preference shifts across the ovulatory cycle were considered an important feature of human sexual selection, directing women's attention towards mates with indicators of "good genes" in their fertile phase, when conception is possible. However, several recent studies on masculine faces, bodies or behaviors have failed to find evidence supporting this account, known as the *good genes ovulatory shift hypothesis*. Furthermore, evidence that preferences for masculine characteristics in men's voices are related to women's cycle phase and hormonal status is still equivocal. Here, we report two independent within-subject studies from different labs with large sample sizes ($N = 202$ tested twice in Study 1; $N = 157$ tested four times in Study 2) investigating cycle shifts in women's preferences for masculine voices. In both studies, hormonal status was assessed directly using salivary assays of steroid hormones. We did not find evidence for effects of cycle phase, conception risk or steroid hormone levels on women's preferences for masculine voices. Rather, Study 2 suggests cycle shifts in women's attraction to men's voices regardless of masculine characteristics, though Study 1 provided only partly evidence for such attraction shifts. Women's relationship status and self-reported stress did not moderate these findings, and the hormonal pattern that influences these shifts remains somewhat unclear. We consider how future work can clarify the mechanisms underlying psychological changes across the ovulatory cycle.

Keywords: steroid hormones, fertility, attractiveness, voice masculinity, mate preferences

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Highlights:

- Tested the robustness of ovulatory cycle shifts in women's mate preferences for masculine voices
- Two large independent studies, using natural and manipulated stimuli
- Evaluated direct hormone assessments and moderator variables
- No evidence for cycle shifts in women's preferences for vocal masculinity
- Cycle shifts in women's attraction, regardless of voice masculinity, not moderated by relationship status or self-reported stress

Introduction

Whether women's mate preferences change across the ovulatory cycle has been a central question in the human evolutionary sciences over the last decades. While it seems robust that women experience greater levels of sexual desire and interest when fertile (e.g. Arslan et al., 2017; Jones et al., 2018b; Roney & Simmons, 2013; 2016), it remains unclear if any mate preference shifts exist. Recent studies have cast doubt on the existence of cycle shifts in preferences for masculine faces, bodies and behavioral displays (e.g. Jones et al., 2018a; Jünger et al., 2018a; 2018b; Marcinkowska et al., 2016; 2018; Muñoz -Reyes et al., 2014), and called attention to methodological criticisms of prior studies. Inconsistencies in the literature are reflected, for instance, in the outcome of two recent meta-analyses, which reached opposite conclusions about whether women's ovulatory cycle phase reliably influences their judgments of men's attractiveness (Gildersleeve et al., 2014; Wood et al., 2014). In the current manuscript, we tested cycle shifts in women's preferences for masculine voices in two large within-subjects studies from different labs, using natural as well as manipulated voice recordings as stimuli, and also examined hormone concentrations and other possible moderator variables.

Theoretical background

Systematic changes in women's sexual interests across the ovulatory cycle have been intensively investigated. In several studies, women experienced heightened sexual interest during their fertile phase, compared to their non-fertile phases (most notably the luteal phase). More precisely, when fertile, women reported higher extra-pair desire (Gangestad et al., 2002; 2005; Grebe et al., 2016; Haselton & Gangestad, 2006; Shimoda et al., 2018), in-pair as well as extra-pair desire (Arslan et al., 2017; Roney & Simmons, 2016) or general sexual desire (Jones et al., 2018; Roney & Simmons, 2013), which was also found to be linked to their ovarian hormone levels (Jones et al., 2018b; Roney & Simmons, 2013; 2016). To describe differences in sexual psychology and behavior on fertile vs. non-fertile days, Thornhill and

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Gangestad (2008) proposed the concept of *dual sexuality*. While sexual behavior outside the fertile phase may have evolved for pair-bonding purposes (Grebe et al., 2016), the most direct benefit for sexual behavior within the fertile phase is conception (Roney & Simmons, 2013).

Women are thus predicted to change their mate preferences across the ovulatory cycle. When fertile, their sexual interests should hypothetically be directed preferentially towards mates who possess indicators of high genetic quality to achieve fitness benefits for their offspring (Haselton & Gangestad, 2006). In contrast, sexual interests within the non-fertile phases should be directed to long-term mates with a high potential and willingness to provide parental effort (Gildersleeve et al., 2014; Thornhill & Gangestad, 2015). Since ovulatory shifts are predicted to aid in obtaining good genes, potentially from extra-pair copulations (Pillsworth & Haselton, 2006), we will further call this concept the *good genes ovulatory shift hypothesis* (GGOSH; Arslan et al., 2017).

There are several characteristics that have previously been proposed as markers of good genes in men, including higher levels of testosterone (Thornhill & Gangestad, 1993), physical attractiveness (Gildersleeve et al., 2014; Haselton & Gangestad, 2006), low fluctuating asymmetry (Rhodes et al., 2001), muscularity, physical strength, and psychological traits that promote intrasexual competitiveness (Gangestad et al., 2007). Prior studies found evidence for the GGOSH: in the fertile (late follicular) phase, women reportedly shift their preferences toward putative indicators of men's genetic quality, including masculine, dominant-appearing faces (Penton-Voak et al., 1999; Penton-Voak & Perrett, 2000), voices (Feinberg et al., 2006; Pisanski et al., 2014; Puts, 2005; 2006), bodies (Gangestad et al., 2007; Little et al., 2007; Pawlowski & Jasienka, 2005), odor (Gangestad & Thornhill, 1998; Havlicek et al., 2005; Thornhill et al., 2013) and behavioral displays (Gangestad et al., 2004; 2007).

However, some purported indicators of good genes are controversial because reported findings challenge the hypothesis that they actually signal heritable fitness benefits and

immunocompetence (Scott et al., 2012; 2014; Simmons et al., 2011; Wood et al., 2014).

Additionally, the GGOSH itself has been questioned in recent research (Havlíček et al., 2015; Roney & Simmons, 2017). Moreover, several studies raise skepticism about the robustness of preference shifts because of failing replications of prior findings for masculine or symmetrical faces (Harris, 2011; 2013; Jones et al., 2018a; Marcinkowska et al., 2016; 2018; Muñoz - Reyes et al., 2014; Peters et al., 2009), bodies (Jünger et al., 2018b; Marcinkowska et al., 2018; Peters et al., 2009), and behaviors (Jünger et al., 2018a). Furthermore, two large recent studies suggest that women's attraction to men in general, rather than their mate preferences, shifts across the ovulatory cycle (Jünger et al., 2018a; 2018b).

Additionally, two meta-analyses (Gildersleeve et al. 2014; Wood et al. 2014) came to opposite conclusions regarding ovulatory cycle shifts in women's mate preferences. Wood and colleagues (2014) evaluated 58 independent reports (45 published, 13 unpublished), and concluded that the results of the meta-analysis were largely unsupportive for the GGOSH. In the other meta-analysis, Gildersleeve et al. (2014) analyzed a total sample of 134 effects from 38 published and 12 unpublished studies. This analysis concluded that ovulatory cycle effects are robust and not due to publication bias alone (as indicated by p-curve analysis; see Simonsohn et al., 2014). However, reported cycle shifts reached significance only for preferences for body masculinity, reached marginal significance for behavioral dominance, and were only partially supported for facial masculinity (Gildersleeve et al. 2014). Results from this meta-analysis further indicated no support for cycle shifts for facial symmetry and vocal masculinity. The authors attributed this null effect to an underpowered analysis. Given this mixed pattern of findings and the centrality of putative ovulatory shifts in current theorizing about human sexual selection, it is clear that there is an urgent need for further research to determine a) whether women's preferences for masculine features change over the ovulatory cycle, and b) the hormonal correlates of any potential cycle shifts in women's mate preferences.

Preference shifts for voice masculinity

Human voices are highly sexually dimorphic. Sexual dimorphism in vocal anatomy may have been favored by sexual selection because low frequency male vocalizations intimidate rivals and/or attract females (Puts et al., 2016). Masculine voices are characterized by both a lower fundamental frequency and lower, more closely spaced formant frequencies. Fundamental frequency (F_0), the rate of vocal fold vibration during phonation, is the acoustic measure closest to what we perceive as pitch. In males, F_0 is related to testosterone throughout pubertal development (Butler et al. 1989; Harries et al., 1997; 1998; Hodges-Simeon et al., 2015) and during adulthood (Dabbs & Mallinger, 1999; Evans et al., 2008; Puts et al., 2012; 2016). Lower and more closely spaced formant (resonant) frequencies indicate a longer vocal tract and have also been shown to independently increase perceived masculinity (Collins, 2000) and dominance (Cheng et al., 2016; Puts et al., 2006; 2007; Tusing & Dillard, 2000). In such research, formants are often summarized by the composite metric formant dispersion (D_f , the average distance between consecutive formant frequencies computed across the first N , usually four, formants). Hence, the GGOSH would suggest that fertile women should be especially attracted to men with lower F_0 and lower D_f . If preference shifts across the ovulatory cycle for masculine voices occur, then they should be mediated by ovarian hormonal changes. Previous studies report that estradiol, progesterone and the estradiol-to-progesterone-ratio (henceforth E/P) are likely candidates for mediating changes in women's mate preferences for voice masculinity over the cycle (e.g. Feinberg et al., 2006; Pisanski et al., 2014; Puts et al. 2013). Estradiol peaks in women's late follicular (fertile) phase and exhibits a smaller increase during the mid-luteal phase. Progesterone levels are usually lower throughout the follicular phase and increase in the luteal phase.

Surprisingly, although null effects for masculine voices in prior studies were attributed to an underpowered analysis (Gildersleeve et al., 2014), there is a lack of published large,

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

high-powered, within-subject studies investigating preference shifts for masculine voices. However, there are three prior studies that investigated possible cycle shifts for masculine voices and interpreted their results as evidence for mate preference shifts across the ovulatory cycle: Puts (2005) conducted a between-subject study with $N = 136$ female participants ($n = 38$ in the fertile group, $n = 98$ in the non-fertile group) who rated men's voice recordings. The recordings were manipulated (raised or lowered) in both F_0 and D_f (see also Puts et al., 2006) and were rated for short-term as well as long-term attractiveness. Women's conception risk was assessed as a continuous measure, but then participants were categorized to cycle phases. Conception risk was calculated via backward counting from the next estimated menstrual onset. Results showed significant cycle shifts: Women preferred men's lowered pitch voices only when they rated them in their fertile phase and for potential short-term relationships ($p = .020$).

Feinberg and colleagues (2006) reported a within-subjects study with $N = 26$ female participants who completed four to six testing sessions resulting in a total of 41 fertile phase sessions ($n = 25$) and 86 non-fertile phase sessions ($n = 25$). However, average scores within each phase were used if a woman was tested more than one time per cycle phase. Cycle phase (fertile vs. non-fertile) was classified via backward counting. Participants rated the general attractiveness of voice recordings that were manipulated in voice pitch and formant frequencies. Results indicated that women generally preferred masculinized male voices to feminized male voices. Notably, cycle shifts for masculine voices were reported only when estrone-3-glucuronide concentrations (E3G, the primary urinary metabolite of estradiol) were included as a covariate in the analyses ($p = .012$), showing that shifts are stronger for women with lower E3G concentrations. Effects were not significant when pregnanediol-3-glucuronide concentrations (P3G, the primary urinary metabolite of pregnanediol) was included as a covariate ($p = .063$), or in an analysis without covariates ($p = .253$).

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Using a within-subject design with five weekly test sessions per participant, Pisanski and colleagues (2014) reported that changes in estradiol, but not progesterone, trended toward predicting stronger preferences for manipulated masculine voices in a sample of 62 women ($p = .055$). Crucially, this effect did not reach significance, and the authors also observed no significant effect of progesterone, testosterone or E/P on preferences for manipulated masculine voices. However, congruent with the results of Feinberg and colleagues (2006), women generally preferred masculinized over feminized voices, regardless of hormone levels.

Taken together, these studies do not provide strong evidence for cycle shifts in preferences for masculine voices. As Gildersleeve and colleagues (2014) noted, sample sizes tended to be small, with limited test trials in the experimental designs (e.g. 12 trials; Pisanski et al., 2014). In addition, averaging participant ratings of voices (Feinberg et al., 2006; Pisanski et al., 2014) further reduces the statistical power. Moreover, recent research has pointed out additional methodological issues underlying prior cycle shift studies (Blake et al., 2016; Gangestad et al., 2016; Harris, 2013; Shimoda et al., 2018). First, although backward counting was used as a superior means of estimating cycle phase compared to forward counting (Gangestad et al., 2016), authors did not use luteinizing hormone (LH) urine tests to validate the fertile phase estimates, even though a preovulatory surge of LH clearly demarcates distinct cycle phases. Second, the only study that reported a significant preference shift for masculine voices (Puts, 2005) lacks a direct assessment of steroid hormones to analyze mediating effects. Third, effect sizes or 95% confidence intervals of the observed preference shifts were not reported, which makes the reported effects harder to interpret. One would expect cycle shift effect sizes to be rather small (Jünger et al., 2018b), but since prior studies worked with relatively small sample sizes, they may not have had the statistical power to reveal such effects. More precisely, estimates in these small samples would have to be large to reach statistical significance. Consequently, published effects might have been false positives or due to publication bias. Fourth, prior studies used manipulated voices or a

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

combination of manipulated and natural voice recording (Puts, 2006) rather than natural voice recordings alone. It is up for debate to what degree computer-manipulated voices have ecological validity, but in any case natural voices should also be used to ensure that results can be transferred to real-life mate preferences. Considering all of these potential methodological problems and the incongruence in reported results, the associations between women's ovulatory cycle, steroid hormone levels, and mate preferences for masculine voices remains unclear.

Overview over the present studies

In the present studies, we aim to clarify a) whether women's attraction to and/or preferences for masculine voices shift across the ovulatory cycle, b) which hormonal changes might underlie these shifts, and c) which moderators influence these shifts. In what follows, we report two large, independent studies from different labs at two different institutions. Both studies employed a within-subject design with large sample sizes, direct hormonal assessments across one (Study 1) or two (Study 2) ovulatory cycles, and backward counting methods to estimate women's fertility. Study 1 included conception risk as a continuous measure and used voice recordings that were manipulated in F_0 and D_f , while Study 2 included estimated cycle phase (validated with LH tests) as a dichotomous measure of fertility and used natural stimuli. Women's relationship status and self-reported stress are tested as possible moderator variables of ovulatory cycle shifts in women's preferences in Study 2. Additionally, Study 2 was pre-registered¹; open data and material for both studies can be found at the Open Science Framework (<https://osf.io/egjwv>).

Study 1

Method

Participants

¹ This pre-registration also contained further hypotheses that are not part of the present paper.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

A total of 202 women ages 18 to 27 years ($M = 19.56$ years; $SD = 1.59$) participated in this study as part of a larger study at Michigan State University. All participants were exclusively or predominantly heterosexual and normally cycling. They were recruited via print advertisements and the MSU Psychology Department undergraduate subject pool. Informed consent was obtained from participants using procedures approved by the Institutional Review Board of Michigan State University. Participants were scheduled for two laboratory sessions according to self-reported ovulatory cycle length and date of the beginning of last menstrual onset. One laboratory session was scheduled within one day of expected peak estradiol production during the fertile phase, and the other session was scheduled within two days of expected peak progesterone production (mid-luteal phase), according to the methods in Puts (2006). Session order was counterbalanced across participants, such that half of the participants started in their presumed fertile phase and the other half in their presumed luteal phase. Sessions occurred between 1:00 PM and 4:00 PM in order to minimize the influence of circadian hormonal fluctuations.

Saliva collection and hormonal analysis

Saliva collection and hormonal analysis are described in Puts et al. (2013). Briefly, approximately 9 ml of saliva was collected from each participant in sodium azide-treated polystyrene test tubes. Participants were asked not to eat, drink (with the exception of plain water), smoke, chew gum, or brush their teeth for at least 1 hour prior to each session to avoid contamination of saliva samples. To stimulate saliva flow, participants rinsed their mouths with water, and were provided with a piece of sugar-free Trident chewing gum (inert in salivary hormone assays). The tube was capped and left upright at room temperature for 18–24 h to allow mucins to settle. Tubes were then frozen at -20°C until analysis by the Neuroendocrinology Assay Laboratory at the University of Western Ontario, Canada. Progesterone was assayed using ^{125}I Coat-A-Count assay kits (Diagnostic Products Corporation, Los Angeles, CA) modified for use with saliva (e.g. as in Hampson et al., 2005;

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Oinonen & Mazmanian, 2007). Similar to previous research (e.g., Finstad et al., 2009), estradiol was assayed using 125I Ultra-Sensitive E2 RIA DSL-4800 kit (Diagnostic Systems Laboratories, Webster, TX) modified for use with saliva. Each sample was assayed twice to verify replicability, and average hormone levels for each sample were used in our analyses. Assay sensitivities were 0.65 pg/ml and 5 pg/ml, and intra-assay coefficients of variation (CV) were 5.1% and 10.7%, for estradiol and progesterone, respectively. Seven participants were excluded from subsequent hormone analysis due to not providing a saliva sample in both sessions, leaving a total of 195 women. Hormone values were positively skewed and thus log10-transformed.

Measuring conception risk using backward counting

Conception risk was estimated using backward counting. In order to schedule their first session, women were asked to report the date of the onset of their last and their typical cycle length. The day of their next menstrual onset was estimated by adding one typical cycle length to the reported date of last menses. Each participant's day of ovulation was estimated by assuming that ovulation occurs 15 days prior to their next predicted menses date. Next, a conception risk value was assigned accordingly, based on published estimates of the probability of unprotected intercourse producing a conception on that day of the cycle (as in Puts, 2005). Women who did not report the date of their menstrual onset ($n = 38$) were excluded from subsequent conception risk analyses because conception risk could not be calculated. The average length of the ovulatory cycle (average cycle length; henceforth ACL) for women ages 20-24 years old is approximately 30.3 days ($SD = 4.11$ days; based on a study of 30,655 recorded ovulatory cycles from 2,316 women; Chiazze et al., 1968). Based on these findings, women who reported ACLs greater than 35 days were excluded from subsequent counting analyses ($n = 5$). Other women were excluded from subsequent conception risk analysis due to missing data ($n = 21$), suspected dishonest responses about last menstrual onset ($n = 18$), abnormal ($n = 10$) or irregular ovulatory cycle lengths ($n = 10$).

Thus, due to highly stringent criteria for evaluating the influence of conception risk on cyclic variation in preferences, in total 102 participants were excluded from the subsequent conception risk analyses, leaving a final sample for these analyses of 100 women.

Voice recordings and manipulation

Six male voices were recorded as described in Wolff and Puts (2010), reading an excerpt from a standard voice passage (Fairbanks, 1960). Each voice recording was analyzed and manipulated using Praat (v. 4.4.06; Boersma & Weenink, 2006). Pitch floor and ceiling were 75 Hz and 300 Hz, in accordance with programmers' recommendations, or otherwise default settings were used. Formants were measured using the long-term average spectrum (González, 2004; Xue & Hao, 2003), and D_f was computed by taking the average distance between each of the first four formants (Fitch, 1997). For unmanipulated voices, mean F_0 was 109.9 (range = 97.8–122.1, SD = 10.0), and mean D_f was 1,003.5 (range = 941.7–1,072.7, SD = 51.6). For the current study, each of the six voices was raised and lowered using just-noticeable-difference (JND) parameters from Puts et al. (2007): F_0 was raised and lowered 1.2 semitones, while D_f was manipulated with a 4% change. Thus, from each of the original voices, four versions were produced: raised F_0 , lowered F_0 , raised D_f , and lowered D_f , for a total of 24 voice recordings. These recordings were distributed into two stimulus sets of 12 recordings, each set comprising 6 raised F_0 with 6 lowered F_0 and 6 raised D_f with 6 lowered D_f .

Procedure

Each participant was seated at a computer station and provided Sennheiser HD280 Pro headphones. The experiment was computerized and participants were instructed using the following script:

“Please put on the headphones. You are about to hear voice recordings from several men. Please rate how attractive you think each man would be for a short-term, purely

sexual relationship, such as a one-night stand (even if you are not interested in such a relationship)."

After listening to each voice recording, participants rated each voice on a 10-point Likert-scale, from "extremely attractive" (coded as 1) to "extremely unattractive" (coded as 10). We reverse-coded the scale for our analyses for an easier understanding of the results. In order to reduce the chance that participants would recognize the voices in each of the voice manipulations, the voice clips were presented in two separate blocks, with an unrelated memory task between each block. Each block consisted of 12 trials with 6 F_0 and 6 D_f manipulations and each speaker represented by one F_0 manipulation and one D_f manipulation. Hence, if for example, in the first block the raised F_0 manipulation was presented for a particular speaker, then the lowered F_0 manipulation was presented in the second block. Participants rated all 12 recordings during both laboratory visits in the same order.

Statistical analyses

All analyses in the current manuscript were calculated with the statistic software R 3.4.0 (R Core Team, 2016). The following packages were used: lme4 1.1-13 (Bates et al., 2014), lmerTest 2.0-33 (Kuznetsova et al., 2013), psych 1.7.5 (Revelle, 2016), dplyr (Wickham, 2011).

Results

Ovulatory cycle shifts in women's mate attraction

First, we tested whether ratings were generally related to conception risk or steroid hormone levels, independent of voice manipulations, in three separate models. All models included attractiveness ratings as the dependent variable, and a random intercept per female rater as well as for male stimulus. Model 1 additionally included women's conception risk as a fixed effect. The analysis showed no significant effect: Ratings were not higher when conception risk was high ($\gamma = -0.33$, $SE = 0.38$, $t = 0.87$, $p = .386$, $95\%CI = [-1.07; 0.41]$). These results indicate that ratings did not differ with variation in women's conception risk.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Model 2 included estradiol and progesterone, Model 3 E/P as predictors². Results show no effect of estradiol or E/P, but importantly, a significant negative effect of progesterone, suggesting higher ratings on average when progesterone levels were lower (Table 1).

Table 1

Multilevel regression analyses of attractiveness ratings as a function of estradiol and progesterone (Model 2) or E/P (Model 3).

	γ	SE	t	p	95% CI
Estradiol	-0.17	0.11	-1.53	.127	[-0.39; 0.05]
Progesterone	-0.23	0.10	-2.25	.024	[-0.43; -0.03]
E/P	0.05	0.08	0.63	.529	[-0.11; 0.22]

Note. All variables had 8,820 observations, (195 participants x 2 test sessions x 12 stimuli x 2 masculinity manipulations – missing values).

Ovulatory cycle shifts in women's mate preferences for masculinized voices

Next, we tested if participants showed preference shifts across the ovulatory cycle for voice pitch or formant dispersion across six separate models (discussed below as Models 4 through 9). Again, female raters and male stimuli were treated as random effects. The first two models included women's conception risk, voice manipulation (masculinized vs. feminized F_0 in Model 4, D_f in Model 5), as well as their interaction as fixed effects. The next two models included women's hormone levels (estradiol and progesterone), voice manipulation (masculinized vs. feminized F_0 in Model 6, D_f in Model 7), as well as their interaction as fixed effects. Then, we additionally calculated two models including E/P, voice manipulation (masculinized vs. feminized F_0 in Model 8, D_f in Model 9), as well as their interaction as fixed effects. Multilevel within-subjects comparisons showed no significant interactions between conception risk and F_0 or D_f manipulation (Table 3), suggesting no significant cycle shift in women's preferences for masculinized vs. feminized voices. Additionally, there were no significant main effects for women's conception risk or D_f manipulation. However, there was a significant main effect for F_0 manipulation, showing that

² We decided to analyze the effect of hormones on ratings in two separate models because of possible problems of multicollinearity ($r = .61$ for estradiol and E/P; $r = -.16$ for progesterone and E/P).

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

voices with masculinized voice pitch were rated as more attractive, independent of women's conception risk.

Table 3

Multilevel regression analyses of attractiveness ratings as a function of conception risk and manipulated voice pitch (Model 4) or formant dispersion (Model 5).

	γ	SE	T	p	95% CI
Voice pitch model					
Conception risk	0.07	0.69	0.10	.921	[-1.28; 1.42]
F_0	-1.52	0.09	-16.09	<.001	[-1.70; -1.33]
Conception risk x F_0	-0.25	0.91	-0.28	.784	[-2.03; 1.53]
Formant model					
Conception risk	-0.56	0.66	-0.86	.390	[-1.85; 0.72]
D_f	0.16	0.09	1.78	.075	[-0.02; 0.33]
Conception risk x D_f	-0.02	0.86	-0.02	.984	[-1.70; 1.67]

Note. F_0 = fundamental frequency (voice pitch), D_f = formant dispersion. All variables in voice pitch model had 2,388 observations, formant model 2,383 observations (each 100 participants x 2 test sessions x 12 stimuli – missing values).

Hormonal analyses revealed no significant interactions between hormone levels and F_0 or D_f manipulation (Table 4 and 5), indicating no hormonal regulated preference shifts. Additionally, there were no significant main effects of D_f manipulation, but a significant main effects of F_0 (Models 4 and 6), showing that voices with masculinized voice pitch were rated as more attractive than the same voices with feminized voice pitch. For hormone levels, we found a significant negative main effect for progesterone in Model 6 (with manipulated F_0) but not in Model 7 (with manipulated D_f), showing that ratings were higher when progesterone was lower. We, again, did not find a significant effect for estradiol in Model 6 or Model 7. Additionally, we found a significant main effect of E/P in Model 8 (with manipulated F_0) but not in Model 9 (with manipulated D_f), showing that ratings were higher when E/P was higher (usually in the fertile phase).

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Table 4

Multilevel regression analyses of attractiveness ratings as a function of estradiol and progesterone levels and manipulated voice pitch (Model 6) or formant dispersion (Model 7).

	γ	SE	t	p	95% CI

D_f	-0.13	0.25	-0.53	.599	[-0.62; 0.36]
E/P	-0.02	0.13	-0.14	.893	[-0.28; 0.25]
D_f x E/P	-0.12	0.16	-0.74	.460	[-0.43; 0.19]

Note. F_0 = fundamental frequency (voice pitch), D_f = formant dispersion. All variables in voice pitch model had 4,416 observations, formant model 4,404 observations (each 195 participants x 2 test sessions x 12 stimuli – missing values).

Robustness checks

We conducted further analyses to test the robustness of our results. To ascertain that our results were not driven by order effects of testing sessions or participants' age, we entered session number and participant age (Little et al., 2010) in all of our models. The main effects of progesterone and E/P from Models 2 and 3 disappeared, but those from Models 6 and 8 remained significant. However, all other results remained virtually identical (significant main

effect for F_0 as well as all non-significant effects) and can be found in the supplement (Tables S1 – S6).

Study 2

Study 2 was conducted at the University of Goettingen, independently from Study 1, and differed from Study 1 in several ways. First, Study 2 used unmanipulated voice recordings as stimuli, which enabled us to explore preferences for other acoustic parameters, including jitter and shimmer (cycle-to-cycle variation in F_0 and amplitude, respectively), which are associated with pathological voice quality (Dejonckere et al., 1996; Michaelis et al., 1998). Second, baseline testosterone levels of the men who provided the voice stimuli were assessed along with the other vocal cues. This provided a direct test of whether preference shifts occur for men with higher baseline testosterone levels, which are generally found to be negatively associated with F_0 (Butler et al., 1989; Dabbs & Mallinger, 1999; Harries et al., 1997, 1998).

Third, in addition to estradiol and progesterone, participants' testosterone and cortisol levels were also assessed. Like estradiol, testosterone can show mid-cycle peaks and has been found to predict women's preferences for masculine faces (Bobst et al., 2013; Welling et al., 2007). Recent research also suggests that cortisol and psychological stress should be measured in studies on hormones and female mate preferences. Stress elevates cortisol levels (Herrera et al., 2016), which may inhibit estradiol production in young women (Roney & Simmons, 2015) and decrease women's preferences for male facial masculinity (Ditzen et al., 2017, but see Jones et al., 2018a).

Fourth, we ascertained women's relationship status. Recent studies reported ovulatory cycle shifts in attraction to men (Jünger et al., 2018a; 2018b) and in sexual desire (Roney & Simmons, 2016) that were evident only in partnered women. Furthermore, partnered women were found to be more likely to have sexual fantasies about men other than their primary partner (Gangestad et al., 2002), rate the odor of dominant men as sexy (Havlíček et al.,

2005), and report stronger masculinity preferences than singles (Jones et al., 2018a). By contrast, Jones and colleagues (2018b) reported no evidence for a moderating effect of women's relationship status on general sexual desire. The lack of converging evidence in the literature emphasizes the need for further analyses to evaluate the influence of women's relationship status on cycle shifts in preferences.

Fifth, instead of using conception risk as a continuous measure of fertility, we used cycle phase (validated with LH tests) as a categorical measure, and all participants were investigated in four testing sessions across two ovulatory cycles each (see below for detailed methods). Sixth, besides assessing sexual attractiveness ratings, we also assessed long-term attractiveness ratings for all stimuli.

Pre-registered Hypotheses and Research Questions

Following previous findings of ovulatory cycle shifts in mate preferences, we hypothesize that women in the fertile phase, compared to their luteal phase, will evaluate men's voices as more attractive for short-term sexual relationships (Hypothesis 1). This effect should be mediated by changes in the steroid hormones estradiol and progesterone (Hypothesis 2). Hormone levels of testosterone and cortisol will be analyzed as possible mediators in an exploratory manner. Building on prior studies, we derived cues for which cycle shifts, if existent, should occur: Women in their fertile window should be more sexually attracted to men with a lower fundamental frequency and formant dispersion, as well as a higher baseline testosterone level, compared to low-fertility days of their cycle (Hypothesis 3a). We predict these findings to be robust when controlling for men's age. We will furthermore analyze women's preferences for the voice parameters jitter and shimmer in an exploratory manner. We also state the alternative hypothesis that women in their fertile window, compared to their luteal phase, will not show cycle shifts in their mate preferences regarding men's voice attractiveness for sexual relationships (Hypothesis 3b). One possible moderator for cycle shifts might be women's relationship status. Since it remains unclear if

both single and partnered alter their mating strategies across the cycle, we state two alternative hypotheses: Cycle phase shifts in preferences for short-term mates are larger for partnered women than for single women, or, alternatively, the participant's relationship status does not affect the strength of cycle phase shifts in preferences for short-term mates (Hypotheses 4a and 4b). Moreover, we hypothesized self-reported stress as a moderator of cycle shifts: Cycle shifts should be attenuated when self-reported stress is high (Hypothesis 5). We also predict, as the GGOSH suggests, that preference shifts should be absent or less pronounced when it comes to long-term mate preferences (Hypothesis 6, see Gildersleeve et al., 2014).

Methods

Participants and Recruitment

A total of 157 heterosexual female participants (aged 18-35 years, $M = 23.3$, $SD = 3.4$), out of 180 recruited at the University of Goettingen, finished all sessions and were therefore included in further analyses (this sample is the same as in Jünger et al., 2018a and b). Seventeen women who attended only the introductory session of the study dropped out before participation (six fulfilled one of the exclusion criteria below, four quit the study without further reasons, four did not respond to emails, three had scheduling problems). Another six dropped out during the study because of completing only the first testing session (four had scheduling problems, two did not respond to emails after the first session). Based on the inclusion criteria of other ovulatory cycle studies, our participants had to fit the following preregistered criteria: female, between 18 and 30 years³ old, naturally cycling (no hormonal contraception for at least three months, not expected switch to hormonal contraception during the study, no current pregnancy or breastfeeding, no childbirth or breast-feeding during the previous three months, not taking hormone-based medication or anti-depressants).

³ One of the participants reported being 35 years old. We included her data because she met all other inclusion criteria and had positive LH tests. Excluding her data did not alter the results.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Additionally, participants had to report that their ovulatory cycles had a regular length between 25 and 35 days during the last 3 months. At the beginning of the study, 75 of the participants reported being in a relationship, 82 reported being single. Upon completion of all sessions, participants received a payment of 80€ or course credit, and a 3D printed figure of themselves.

Procedure

All participants took part in five individually scheduled sessions. In the first session participants received detailed information about the general procedure, duration of the study and compensation. All participants signed a written consent document, and the ethics committee of the Institute of Psychology at the University of Goettingen approved the protocol (no. 144). The experimenter explained the ovulation tests and checked the inclusion criteria. To count the days to the next ovulation and plan the dates of the experimental sessions, cycle length as well as the dates of the last and the next menstrual onset were assessed. Finally, demographic data were collected.

Sessions two to five, the computer-based testing sessions, took place across two ovulatory cycles per participant, once per cycle during the late follicular (fertile) phase and once during the luteal phase. To control for possible effects of diurnal changes in hormone levels, all sessions took place in the second half of the day (mainly between 11.30 am and 6 pm). When arriving at the lab, participants first completed a screening questionnaire, assessing their eligibility and some control variables for the saliva samples (Schultheiss & Stanton, 2009). Next, the saliva samples were collected via passive drool before the participants started their first rating task⁴. In preparation for listening to the unmanipulated voice recordings, participants were instructed to evaluate the men's attractiveness as they

⁴The described study on ovulatory cycle shifts for voice masculinity was one part of a larger study (see pre-registration). Participants also had to complete other rating tasks and anthropometric data was collected between these tasks. The duration of one experimental session was approximately 2-2.5h.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

perceived it “in that moment”, independent of their own current relationship status or general interest in other men. Participants were then presented with the voice recordings in a randomized order. After listening to a voice, participants rated it for sexual attractiveness (assessing short-term attractiveness) and for long-term attractiveness using an eleven-point Likert scale from -5 (*extremely unattractive*) to +5 (*extremely attractive*). Definitions of sexual attractiveness and attractiveness for a long-term relationship were provided prior to the ratings and read as follows:

- a) *Sexually attractive*: Men who score high would be very attractive for a sexual relationship that can be short-lived and must not contain any other commitment. Men scoring low would be very unattractive for a sexual relationship.
- b) *Attractive for a long-term partnership*: Men who score high would be very attractive for a committed relationship with a long-term perspective. Men scoring low would be very unattractive as a long-term partner.

After each session, the appointment for the next session was arranged individually based on participant’s ovulatory cycle.

Furthermore, all participants of the current study were asked to participate in a separate daily online diary study (Arslan et al., 2016) that was conducted in parallel to the described lab study. Within this diary study, participants had to fill out a questionnaire about daily feelings and behavior across 70 days. We used the stress ratings from this study for further analyses (see below).

Measures

Ovulatory cycle phase

Women’s cycle phase was determined by the reverse cycle day method, based on the estimated day of the next menstrual onset (Gildersleeve et al., 2012) and confirmed by highly sensitive (10 mIU/ml) urine ovulation test strips from purbay®, which measure luteinizing

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

hormone (LH). These LH tests were conducted privately at home on the estimated day of ovulation and the four days prior to that, and results were self-reported by the participants. The study investigated two ovulatory cycles in which every participant reported to the lab twice: Once while being fertile (at the days prior to ovulation, usually reverse cycle days 16-18, with reverse cycle day 16 as the ideal date) and once when not fertile (during the luteal phase, after ovulation and prior to the next menstrual onset, usually reverse cycle days 4-11, with reverse cycle days 6 to 8 as the ideal dates). An Excel sheet was used to compute the acceptable days for the testing sessions and track whether a participant started in her fertile or luteal phase. Of all participants who finished all sessions, 66 participants started with the first session in their luteal phase, and 91 started in the fertile phase.

Hormone measures

We collected four saliva samples from each participant (one per testing session) prior to the rating tasks. Contamination of saliva samples was minimized by asking participants to abstain from eating, drinking (except plain water), smoking, chewing gum or brushing teeth for at least one hour before each session. The samples were stored at -80°C directly after collection until shipment on dry ice to the Kirschbaum Lab at Technical University of Dresden, Germany, where estradiol, progesterone, testosterone and cortisol were assessed via liquid chromatography mass spectrometry (LCMS; Gao et al., 2015). Because the LCMS analysis of estradiol detected only 22% of all possible values, the samples were reanalyzed using the highly sensitive 17 β -estradiol enzyme immunoassay kit (IBL International, Hamburg, Germany). These latter estradiol values were used in subsequent analyses. Hormone levels were skewed, therefore, we centered all hormone values on their subject-specific means and scaled them afterwards (i.e. divided them by a constant), so that the majority of the distribution for each hormone varied from -0.5 to 0.5 to facilitate calculations in the linear mixed models (as in Jones et al., 2018b; and congruent with our approach in Jünger et al., 2018a; 2018b). This is a common procedure to isolate effects of within-subject

changes in hormones, avoiding the influence of outliers on results and dealing with the non-normal distribution of hormone levels. Hormone levels were nearly normally distributed afterwards, a figure showing the distribution of hormone levels after this procedure can be found in the supplement (Figure S1). Importantly, this procedure did not change any findings compared to analyses with untransformed hormone values. The R code for this procedure can be found in the open script.

Stimuli and masculinity analyses

Seventy-six voices of different men, counting from three to eight in German, recorded as part of the Berlin Speed Dating Study (see Asendorpf et al., 2011 for more details), were presented via headphones (JVC® HA-RX300). We selected recordings from 76 participants out of a pool of 382 by gender (male) and age (between 18 and 30 years old, matching the age of the eligible female participants in the study). Stimulus males' baseline testosterone levels were measured from saliva samples. The samples were analyzed using radioimmunoassay by the Kirschbaum lab at the Technical University Dresden. Each recording was analyzed using Praat software (version 6.0.17). Pitch, floor, ceiling and other settings were set in line with Study 1. Across each recording, we measured mean F_0 (henceforth, F_0 ; $M = 110.74$, range = 85.30–157.48; $SD = 12.66$) and median formant frequencies from which we computed D_f ($M = 1043.19$ Hz, range = 961.67–1137.68, $SD = 30.30$ Hz) as in Study 1, and measured four measures of jitter and five measures of shimmer. All jitter ($r > .97$) and shimmer ($r > .31$) variables were correlated and therefore z -standardized and summed (jitter: $M = 0.00$, $SD = 0.99$; shimmer: $M = -0.02$, $SD = 0.84$). Additionally, we computed formant position (P_f ; $M = 0.00$, range = -1.36–2.96, $SD = 0.68$), the standardized formant value for the first four formants which has been found to be more sexually dimorphic than D_f (Puts, Apicella, & Cardenas, 2012).

Stress ratings

Self-reported stress was measured with one item (“*Today I was stressed out*”) on a five-point Likert-scale (from “*less than usual*” to “*more than usual*”) on a daily basis within the accompanying online diary study (see above) with planned missings⁵. For the analysis, the stress value from the day of the lab testing session was used. If there was no existing value for that specific day, then we averaged the values of the two days before and after the testing day, if available. In total, 54 of the 157 participants were excluded from analyses, 26 because they did not take part in the diary study, 20 because they did not fill out enough days to provide data for at least one fertile and one luteal session, and eight because they took part in the study at another time window (not parallel to the lab study). Sixty-two participants had stress data for at least one fertile and one luteal session, and 41 for all sessions, resulting in an available dataset of 160 cycles (out of 314 possible cycles) in total.

Results

Preliminary Analyses

First, we counted how many cycles were reported as being irregular (more than three days deviation between testing session and a-priori defined windows of appropriate testing days; see section “ovulatory cycle phase”). Even though all participants reported having regular ovulatory cycles in the introductory session, eight women reported irregularity in both investigated cycles, and 32 reported one cycle being irregular, resulting in 48 out of 314 (15.3%) cycles being irregular. Next we checked how many of the participants’ ovulatory cycles had positive LH tests (indicating a LH surge) in the calculated fertile phase to detect non-ovulatory cycles. Twelve participants reported negative LH test results for both investigated cycles, nine reported negative LH tests results for one cycle. In total, the LH tests in 33 of all 314 cycles (10.5%) were negative. Additionally, we checked the temporal

⁵ The participants had to fill out more than 100 items per day. Therefore, we decided to reduce the daily items by planned missings to minimize dropouts while obtaining sufficient data for each item. The relevant stress item was shown on about 40% of all days.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

relationship between the reported day of LH surge and the date of scheduled testing session. Because ovulation usually occurs within 24-36 hours after the observed LH surge, testing sessions that were scheduled more than two days after the surge might have already been in the early luteal phase. Out of the 281 cycles for which an LH surge was observed, thirteen (4.63%) purportedly fertile phase sessions were scheduled three or four days after the LH surge. Therefore, 268 (95.37%) were scheduled within an appropriate range of three days before to two days after the LH surge (in total: $M = -0.12$, $SD = 1.39$ days in relation to the day of the observed LH surge). A histogram showing the distribution of days of fertile phase testing sessions relative to the observed LH surge can be found in the supplement (Figure S2). Participants with irregular cycles, negative LH tests or the risk of early luteal phase instead of fertile phase testing session were included in the main analyses, but excluded in robustness checks.

Main analyses: Cycle shifts in women's attraction and mate preferences

We first tested for possible ovulatory cycle shifts in women's mate attraction to men's voices in general (Hypothesis 1). For the multilevel analyses with attractiveness rating as the dependent variable (Model 1 with sexual attractiveness, Model 2 with long-term attractiveness), female raters as well as the male stimuli were treated as random effects. Women's cycle phase (0 = luteal phase, 1 = fertile phase) was treated as a fixed effect. This analysis showed a significant cycle shift in women's attraction: Ratings for sexual attractiveness were higher in the fertile phase than in the luteal phase of the ovulatory cycle ($\gamma = 0.06$, $SE = 0.02$, $t = 3.37$, $p < .001$, $95\%CI = [0.03; 0.10]$), supporting Hypothesis 1. Similar results were found for the long-term attractiveness ratings ($\gamma = 0.05$, $SE = 0.02$, $t = 2.84$, $p = .004$, $95\%CI = [0.02; 0.09]$), contrary to Hypothesis 6. These results indicate the existence of ovulatory cycle shifts on women's mate attraction to men's voices, independent of the relationship condition (sexual- vs. long-term), such that, overall, fertile women rated men's voices as being more attractive.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

To analyze whether women's mate preferences for specific vocal cues change across the ovulatory cycle (Hypothesis 3), we calculated additional six multilevel models. In all models, female participants as well as male vocal stimuli were treated as random effects, women's cycle phase was treated as fixed effect. Moreover, the vocal masculinity cues F_0 (Model 3 with sexual attractiveness, Model 4 with long-term attractiveness), D_f (Model 5 with sexual attractiveness, Model 6 with long-term attractiveness) and men's baseline testosterone levels (Model 7 with sexual attractiveness, Model 8 with long-term attractiveness) were treated as fixed effects separately. Results show a significant main effect for cycle phase on sexual attractiveness, as well as on long-term attractiveness ratings in each model (Tables 6-8), again supporting Hypothesis 1 and in contrast to Hypothesis 6. Women rated men's voices as more attractive when they were fertile. Moreover, there was a significant effect of fundamental frequency on sexual- as well as long-term attractiveness ratings (Table 6): Voices with lower fundamental frequency were rated as more attractive. The effects of all other mentioned vocal cues did not reach statistical significance. Additionally, none of the vocal cues interacted with cycle phase, indicating that women's mate preferences do not shift for specific cues in men's voices across the ovulatory cycle⁶, in contrast to Hypothesis 3. Results remained stable when controlling for men's age. Moreover, results remained virtually identical when adding all three vocal masculinity cues to the same model at the same time, details can be found in the supplement (Tables S7 and S8).

⁶ In line with Study 1, we also analyzed possible interaction effects of hormone values (estradiol and progesterone or E/P) with all masculine vocal cues (F_0 , D_f , P_f , baseline T) separately in an exploratory manner (each for sexual as well as for long-term attractiveness; $2 \times 4 \times 2 = 16$ additional models). None of these models revealed any significant interaction effect, again suggesting no preference shifts for masculine voices.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Table 6

Multilevel regression analyses of attractiveness ratings as a function of cycle phase and men's voice pitch.

	γ	SE	t	p	95% CI
Short-term					
Cycle phase	0.06	0.02	3.37	<.001	[0.03; 0.10]
Men's F_0	-0.65	0.12	-5.46	<.001	[-0.89; -0.42]
Cycle phase x men's F_0	-0.00	0.02	-0.19	.850	[-0.04; 0.03]
Long-term					
Cycle phase	0.05	0.02	2.84	.004	[0.02; 0.09]
Men's F_0	-0.59	0.12	-4.93	<.001	[-0.82; 0.35]
Cycle phase x men's F_0	-0.00	0.02	-0.24	.807	[-0.04; 0.03]

Note. F_0 = fundamental frequency (voice pitch). All variables had 47,728 observations (157 participants x 4 test sessions x 76 stimuli).

Table 7

Multilevel regression analyses of attractiveness ratings as a function of cycle phase and men's formant dispersion.

	γ	SE	t	p	95% CI
Short-term					
Cycle phase	0.06	0.02	3.37	<.001	[0.03; 0.10]
Men's D_f	-0.27	0.14	-1.94	.057	[-0.54; 0.00]
Cycle phase x men's D_f	0.01	0.02	0.67	.501	[-0.02; 0.05]
Long-term					
Cycle phase	0.05	0.02	2.84	.004	[0.02; 0.09]
Men's D_f	-0.22	0.14	-1.61	.112	[-0.48; 0.05]
Cycle phase x men's D_f	0.00	0.02	0.14	.890	[-0.03; 0.04]

Note. D_f = formant dispersion. All variables had 47,728 observations (157 participants x 4 test sessions x 76 stimuli).

Table 8

Multilevel regression analyses of attractiveness ratings as a function of cycle phase and men's baseline testosterone.

	γ	SE	t	p	95% CI
Short-term					
Cycle phase	0.06	0.02	3.37	<.001	[0.03; 0.10]
Men's baseline testosterone	0.05	0.14	0.33	.744	[-0.23; -0.32]
Cycle phase x men's baseline testosterone	-0.02	0.02	-1.31	.190	[-0.06; 0.01]
Long-term					
Cycle phase	0.05	0.02	2.84	.004	[0.02; 0.09]
Men's baseline testosterone	0.03	0.14	0.22	.825	[-0.24; 0.30]
Cycle phase x men's baseline testosterone	-0.02	0.02	-0.94	.347	[-0.05; 0.02]

Note. All variables had 47,728 observations (157 participants x 4 test sessions x 76 stimuli).

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Further, because recent research suggests P_f as a superior indicator of vocal masculinity compared to D_f (Puts et al., 2012), we also analyzed possible cycle shifts in mate preferences for men's P_f in two separate models (Model 9 for sexual attractiveness, Model 10 for long-term attractiveness), with cycle phase and P_f as fixed effects, and female participants and male stimuli as random effects. Results (Table 9) again show main effects for cycle phase: higher ratings in the fertile phase. There was neither main effect for P_f , nor a significant cycle phase x P_f interaction, in contrast to Hypothesis 3.

Table 9

Multilevel regression analyses of attractiveness ratings as a function of cycle phase and men's P_f .

	γ	SE	t	p	95% CI
Sexual					
Cycle phase	0.06	0.02	3.37	<.001	[0.03; 0.10]
P_f	-0.38	0.21	-1.87	.066	[-0.79; 0.02]
Cycle phase x P_f	0.00	0.03	0.04	.966	[-0.05; 0.06]
Long-term					
Cycle phase	0.05	0.02	2.84	.004	[0.02; 0.09]
P_f	-0.31	0.20	-1.56	.124	[-0.71; 0.08]
Cycle phase x P_f	-0.01	0.03	-0.21	.830	[-0.06; 0.05]

Note. All variables had 47,728 observations (157 participants x 4 test sessions x 76 stimuli). We dummy-coded the variable cycle phase with 0 = luteal, 1 = fertile.

We also analyzed influences of men's jitter and shimmer (as fixed effects) on attractiveness ratings in an exploratory manner. The main effects of cycle phase stayed significant for sexual and long-term attractiveness. Additionally, we found significant main effects for shimmer (sexual: $\gamma = 0.37$, $SE = 0.16$, $t = 2.25$, $p = .027$, $95\%CI = [0.05; 0.68]$; long-term: $\gamma = 0.37$, $SE = 0.16$, $t = 2.31$, $p = .024$, $95\%CI = [0.06; 0.67]$), suggesting higher ratings when shimmer was high; but not for jitter (sexual: $\gamma = -0.14$, $SE = 0.16$, $t = 0.86$, $p = .391$, $95\%CI = [-0.46; 0.18]$; long-term: $\gamma = -0.10$, $SE = 0.16$, $t = -0.65$, $p = .517$, $95\%CI = [-0.41; 0.21]$). Again, all interactions of cycle phase with vocal cues were not significant, in contrast to Hypothesis 3.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

Next, we calculated Spearman rank correlations between attractiveness ratings in the fertile and those in the luteal phase to better understand the reported cycle effect. Results from this analysis indicate that ranks of the rated voices (from the most to the least attractive voice) did not differ between the fertile and the luteal phase for sexual attractiveness ($r = .99, p < .001$), or for long-term attractiveness ($r = .99, p < .001$). Rather, most of the voices received a slightly better rating in the fertile phase compared to the luteal phase (e.g. sexual attractiveness: $M_{fertile} = -0.33, SD = 1.23, M_{luteal} = -0.40, SD = 1.23, d = 0.05$; long-term attractiveness: $M_{fertile} = -0.29, SD = 1.19, M_{luteal} = -0.34, SD = 1.20, d = 0.04$). These results indicate that women rated the same men as more or less attractive, independent of their cycle phase, suggesting that differential effects of masculinity cues are rather unlikely.

Hormonal influences on cycle shifts

In order to analyze whether steroid hormones mediate effects of cycle phase (Hypothesis 2), we entered cycle phase, estradiol, progesterone, E/P, testosterone, and cortisol as fixed effects into the multilevel model with attractiveness ratings as the outcome variable (Model 11 for sexual attractiveness, Model 12 for long-term attractiveness), and female participants and male stimuli as random effects. Results demonstrate that, in contrast with Hypothesis 2, there were no mediating effects of any hormone levels: results of cycle phase remained significant and effects were even larger than in the model without hormone levels (see Table 10), reinforcing the effect that ratings increased in women's fertile phase compared to ratings in the luteal phase. Moreover, there was a significant positive effect of progesterone on both sexual and long-term attractiveness. Counterintuitively, ratings were higher when progesterone levels were higher. There was an additional effect of E/P ratio on long-term attractiveness, ratings were higher when E/P was lower, again counterintuitively. There were no significant effects of estradiol, testosterone, or cortisol. Again, because of possible problems of multicollinearity ($r = .25$ for estradiol and E/P; $r = -.30$ for progesterone and E/P), we also calculated additional models with estradiol, progesterone, testosterone and

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

cortisol as fixed effects, but excluding E/P, to test the robustness of our effects. Results remained virtually identical and can be found in the supplemental material (Table S9).

However, in line with our reported results in Jünger et al. (2018b), and because results did not change when analyzing hormone values separately, we decided to report the models with all hormones included here.

Table 10

Multilevel regression analyses of attractiveness ratings as a function of cycle phase with hormone levels as possible mediator variables

	γ	SE	t	p	95% CI
Sexual					
Cycle phase	0.10	0.03	4.01	.001	[0.05; 0.15]
Estradiol	-0.03	0.04	-0.72	.472	[-0.10; 0.05]
Progesterone	0.10	0.03	3.16	.002	[0.04; 0.16]
E/P	0.01	0.02	0.32	.752	[-0.04; 0.05]
Testosterone	0.01	0.01	0.66	.510	[-0.02; 0.04]
Cortisol	0.03	0.03	0.81	.417	[-0.04; 0.09]
Long-term					
Cycle phase	0.11	0.03	4.45	<.001	[0.06; 0.16]
Estradiol	0.01	0.04	0.30	.764	[-0.06; 0.08]
Progesterone	0.08	0.03	2.47	.013	[0.02; 0.14]
E/P	-0.06	0.02	-2.63	.009	[-0.11; -0.02]
Testosterone	0.00	0.01	0.30	.764	[-0.02; 0.03]
Cortisol	-0.03	0.03	-0.83	.406	[-0.09; 0.04]

Note. All variables had 40,584 observations (157 participants x 4 test sessions x 76 stimuli – missing values). We dummy-coded the variable cycle phase with 0 = luteal, 1 = fertile. All hormone values were centered to their subject-specific means and then scaled.

Investigating women's relationship status as a possible moderator

To evaluate whether women's relationship status influences ovulatory cycle shifts⁷, we first categorized all women as in a relationship who reported being in an open relationship, in a committed relationship, engaged or married. Relationship status changed for 13 women across the study. Their data were categorized according to their relationship status on the particular testing day. Two multilevel models (Model 13 for sexual attractiveness, Model 14

⁷ Although we originally stated the hypothesis that women's relationship status might moderate preference shifts, we decided to rather report our moderator analyses for attraction shifts, because we did not find any hint for a preference shift in all of our analyses. However, we also investigated possible three-way interactions between cycle phase, relationship status and all masculine vocal cues (F_0 , D_f , P_f , baseline T) separately (each for sexual as well as for long-term attractiveness; 4x2 = 8 additional models). None of these models revealed any significant interaction effect, indicating no preference shifts for masculine voices and no moderation effects of women's relationship status, in contrast to Hypothesis 4a, but supporting Hypothesis 4b.

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

for long-term attractiveness as outcomes) with women's cycle phase and relationship status as fixed effects, and female participants and male stimuli as random effects again showed significant main effects of cycle phase (Table 11). Both sexual and long-term attractiveness ratings were higher in the fertile phase of the ovulatory cycle. There were no significant effects of relationship status (for sexual attractiveness ratings, this variable just failed to reach statistical significance) or of the cycle phase \times relationship status interaction. Therefore, women's relationship status did not moderate the effect of cycle shifts on attractiveness ratings.

Table 11

Multilevel regression analyses of attractiveness ratings as a function of cycle phase and women's relationship status.

	γ	SE	t	p	95% CI
Sexual					
Cycle phase	0.07	0.03	2.63	.009	[0.02; 0.12]
Relationship status	-0.13	0.07	-1.87	.062	[-0.26; 0.01]
Cycle phase x Relationship status	-0.01	0.04	-0.20	.842	[-0.08; 0.07]
Long-term					
Cycle phase	0.09	0.03	3.29	.001	[0.03; 0.14]
Relationship status	-0.11	0.07	-1.64	.100	[-0.25; 0.02]
Cycle phase x Relationship status	-0.06	0.04	-1.69	.091	[-0.14; 0.01]

Note. All variables had 47,728 observations (157 participants \times 4 test sessions \times 76 stimuli). We dummy-coded the variable cycle phase with 0 = luteal, 1 = fertile, and relationship status with 0 = single, 1 = in a relationship.

Self-reported stress

Furthermore, we analyzed whether self-reported stress moderated the relationship between cycle phase and attractiveness ratings (Hypothesis 5). We calculated two further multilevel models (Model 15 for sexual attractiveness, Model 16 for long-term attractiveness ratings). Again, female raters as well as the male stimuli were treated as random effects. Women's cycle phase and self-reported stress ratings were treated as fixed effects. Because many women did not fill out the self-reported stress item for every testing day due to the planned missings design (see Methods), data for only about half of the sample were available. When evaluating sexual attractiveness ratings as the outcome variable, we found significant main effects of cycle phase and self-reported stress, revealing that sexual attractiveness

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

ratings were higher in the fertile phase of the cycle and when self-reported stress was low. However, the interaction between cycle phase and self-reported stress was not significant. When evaluating ratings of male voices on attractiveness for a long-term relationship as the outcome variable, we found significant main effects of cycle phase and self-reported stress, but no statistically significant interaction between the two variables (Table 12). This indicates that women's attractiveness ratings of men's voices for a long-term relationship were higher in the fertile phase of the cycle and, separately, when self-reported stress was low. For both sexual and long-term attractiveness, cycle phase and self-reported stress did not interact, indicating that there was no moderation effect of self-reported stress on cycle effects. These results contradict Hypothesis 5, but show that higher stress has a negative effect on sexual and long-term attraction.

Table 12

Multilevel regression analyses of attractiveness ratings as a function of cycle phase and women's self-reported stress.

	γ	SE	t	p	95% CI
Sexual					
Cycle phase	0.20	0.06	3.14	.002	[0.07; 0.32]
Self-reported stress	-0.05	0.02	-2.15	.032	[-0.09; -0.00]
Cycle phase x Self-reported stress	-0.04	0.03	-1.38	.167	[-0.10; 0.02]
Long-term					
Cycle phase	0.13	0.06	2.00	.046	[0.00; 0.25]
Self-reported stress	-0.04	0.02	-2.01	.045	[-0.09; -0.00]
Cycle phase x Self-reported stress	-0.02	0.03	-0.61	.540	[-0.08; 0.04]

Note. All variables had 24,320 observations (103 participants x 4 test sessions x 76 stimuli – missing values). We dummy-coded the variable cycle phase with 0 = luteal, 1 = fertile.

Further robustness checks

We conducted further analyses to test the robustness of our effects. To rule out the possibility that the results were driven by order effects of testing sessions (in particular, participating in the first session when fertile; Suschinsky et al., 2014), we controlled for cycle phase order in our analyses. For both sexual and long-term attraction, the effect of cycle phase remained stable (sexual: $\gamma = 0.06$, $SE = 0.02$, $t = 3.37$, $p < .001$, $95\%CI = [0.03; 0.10]$; long-term: $\gamma = 0.05$, $SE = 0.02$, $t = 2.84$, $p = .004$, $95\%CI = [0.02; 0.09]$). Moreover, session order

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

affected sexual, but not long-term, attractiveness ratings (sexual: $\gamma = 0.31$, $SE = 0.13$, $t = 2.41$, $p = .016$, $95\%CI = [0.06; 0.57]$; long-term: $\gamma = 0.24$, $SE = 0.14$, $t = 1.69$, $p = .091$, $95\%CI = [-0.04; 0.52]$), showing that sexual attractiveness ratings were higher when participants started in the fertile phase.

Next, we added a variable for values of the first vs. the second tested ovulatory cycle as a fixed effect to our basic model with cycle phase as another fixed effect, female raters and male stimuli as random slopes, to evaluate the influence of testing order on ratings. For both, sexual and long-term attraction, the effects of cycle phase remained stable (sexual: $\gamma = 0.06$, $SE = 0.02$, $t = 3.37$, $p < .001$, $95\%CI = [0.03; 0.10]$; long-term: $\gamma = 0.05$, $SE = 0.02$, $t = 2.84$, $p = .004$, $95\%CI = [0.02; 0.09]$). Values of the first vs. the second cycle affected long-term, but not sexual attractiveness ratings (sexual: $\gamma = -0.02$, $SE = 0.02$, $t = -1.33$, $p = .185$, $95\%CI = [-0.06; 0.01]$; long-term: $\gamma = -0.11$, $SE = 0.02$, $t = -6.02$, $p < .001$, $95\%CI = [-0.15; -0.08]$).

Long-term attractiveness ratings were higher in the first investigated cycle across all participants. Then we conducted our analyses only with women who perfectly met all inclusion criteria ($n = 112$ who reported positive LH tests in their fertile phase and a regular cycle length in both investigated cycles⁸). Nearly all results remained robust across all checks. However, we found a small but significant interaction of cycle phase and men's baseline testosterone levels for short-term attractiveness ratings (Table S11), but opposite to the predicted direction: When fertile, women rated voices of men with lower baseline testosterone levels as being more sexually attractive ($p = .042$). Moreover, hormone effects on long-term attractiveness ratings did not remain significant (Table S13), but we found a significant negative effect of estradiol on sexual attractiveness ratings ($p = .038$): Ratings were higher when estradiol was lower. For relationship status, we found an additional interaction for long-

⁸ As part of our sampling size determination strategy, we pre-registered that we will also report when effect sizes are notably different within the sample of the first $N = 120$. As 112 out of the first 120 women met all inclusion criteria exactly as pre-registered and do not exceed the number of 120, the reported results for these participants could be seen as the pre-registered sample.

term ratings (Table S14): Fertile single women rated men's voices as more attractive for long-term relationships ($p = .026$). Details and results of all analyses can be found in the supplemental material (Tables S10 – S15).

Discussion

We sought to clarify whether women experience mate preference shifts for male voice masculinity across the ovulatory cycle. We evaluated hormonal influences underlying women's cycle shifts in attraction and preferences for masculine voices and further investigated potential moderators of these effects. We included multiple measures of fertility (conception risk estimated from self-report data, cycle phase confirmed via LH tests and hormone levels assayed from saliva), investigated preferences for natural as well as manipulated stimuli, and employed within-subject designs in two samples that exceed the sizes from previous studies. In both studies, there was no evidence to support the hypothesis that women experience cycle shifts in mate preferences for masculine voices. Further, we report that conception risk was not significantly related to attractiveness ratings in Study 1, but progesterone and E/P influenced attractiveness ratings. However, Study 2 indicated the presence of robust cycle phase shifts in women's overall attraction to men's voices, but not shifts in preferences for specific vocal characteristics. Women's relationship status or self-reported stress did not moderate attraction shifts. We did not find a clear pattern of hormonal influences on attractiveness ratings across the cycle: In Study 1, progesterone significantly and negatively influenced attractiveness ratings, indicating that voice recordings were rated as more attractive when progesterone levels were lower. Additionally, in one model (Model 8), E/P positively predicted attractiveness ratings, whereas there was not significant relationship in two other models. In Study 2, both sexual and long-term attractiveness ratings were higher when progesterone levels were higher, and long-term attractiveness ratings were higher when E/P was lower. However, hormonal predictors of long-term attractiveness ratings did not

remain significant when we analyzed women with positive LH tests and regular cycles only.

In the following, we interpret these findings and highlight implications for future research.

Preference vs. attraction shifts

As in previous work evaluating shifts in mate preferences for body and facial masculinity (Jones et al., 2018a; Jünger et al., 2018b; Marcinkowska et al., 2018; Peters et al., 2009), as well as men's behaviors (Jünger et al., 2018a), we report no effects of cycle phase, conception risk or steroid hormone levels on women's mate preferences for masculine voices across two independent studies. Therefore, we did not find evidence for the GGOSH, even with large samples, multiple time points (i.e. greater power to detect an effect across testing sessions, Gangestad et al., 2016), and highly reliable estimates of cycle phases compared to prior studies that purportedly found evidence for mate preference shifts for masculine voices across the ovulatory cycle. Indeed, in the robustness checks of Study 2, we found an interaction effect between women's cycle phase and men's baseline testosterone levels on sexual attractiveness ratings, but this effect was in the opposite direction than predicted by our hypotheses and the GGOSH: Ratings were higher in the fertile phase when baseline testosterone was low. However, the effect had a rather high p -value (.042), was found in only one of many different models and is counter-intuitive. We therefore suggest that it is a false positive.

Instead of preference shifts, Study 2 suggests a cycle shift in women's overall attraction: Both sexual and long-term attractiveness ratings were higher in the fertile phase, regardless of men's voice pitch, formant dispersion, formant position, or baseline testosterone levels. Similarly, a cycle phase attraction shift was recently reported for body masculinity and men's behaviors within the same dataset (Jünger et al., 2018a; 2018b). These attraction shifts might be connected to fertile phase increases in sexual motivation and desire (Arslan et al., 2017; Jones et al., 2018b; Roney & Simmons, 2013; 2016) and are in line with the motivational priority shift account (Roney & Simmons, 2017). This account, based on

CYCLE SHIFTS IN PREFERENCES FOR VOICE MASCULINITY

evolutionary life history theory, entails a shift in motivational priorities towards mating behavior in the fertile phase of the ovulatory cycle, when conception provides a fitness benefit that outweighs the costs of sex, resulting in increased sexual motivation.

However, we did only find partial evidence for an attraction effect in Study 1. Specifically, ratings were not generally higher when conception risk was higher, but they were higher when progesterone levels were lower (and when E/P was higher, at least in one model), which is usually the case in the fertile phase of the ovulatory cycle. There are several possible reasons why these results differed between the two studies. First, different methods were used in both studies. Study 1 used conception risk as a continuous predictor for fertility measures, manipulated voice recordings of men reading a brief passage, and had two testing sessions per participant. Study 2, contrarily, used cycle phase as a dichotomous predictor for fertility, LH tests to validate the fertile phase, unmanipulated voice recordings of men counting, and investigated two ovulatory cycles (four testing sessions) per participant. Nevertheless, the central conclusions remain, whereby no cycle shifts in preferences were observed in either study. Second, the reported effect sizes for sexual attraction shifts in Study 2 were small (ratings: $\gamma = 0.06$ in the main analyses, $\gamma = 0.09$ in the robustness analyses). Study 1 had a smaller sample size ($n = 100$ for conception risk analyses) as well as fewer test trials and therefore fewer observations than Study 2 (4,771 observations in Study 1; 47,728 observations in Study 2), which makes it more difficult to detect this small effect. However, the differences in observations may overstate the differences in power here, since test power in both studies was fairly high compared to prior studies. Third, although the other explanations seem to be more likely, the attraction shift effect reported in Study 2 might simply not be robust. Hence, further research should test the reliability of attraction shifts across the ovulatory cycle, investigate under which circumstances they occur and whether they correlate with a general fertile phase sexual desire increase.

Hormonal influences

Prior studies have suggested that changes in women's mate preferences and desire are regulated by steroid hormonal changes across the ovulatory cycle (Feinberg et al., 2006; Jones et al., 2018b; Pisanski et al., 2014; Puts, 2005, 2006; Roney & Simmons, 2013, 2016). However, our results did not reveal a clear pattern of hormonal influences on women's attraction across the ovulatory cycle. In fact, we found different results for hormone levels even for different hormone value transformations across the two studies.

Progesterone predicted attractiveness ratings in Study 1 and attraction shifts in Study 2, but in different directions: negatively in Study 1 and positively in Study 2. These contradictory results for sexual attractiveness ratings remained significant in the robustness checks. The positive influence of progesterone in Study 2 is particularly counterintuitive, as progesterone levels are generally higher in the luteal phase, but we found generally higher attractiveness ratings in the fertile phase. Typically, this effect has been found in the opposite direction in prior studies and in Study 1. Critically, the negative association reported in Study 1 aligns more closely with the theoretical assumptions and findings of previous work.

Besides the puzzling effects of progesterone, E/P positively influenced attractiveness ratings in Study 1 and negatively influenced long-term attractiveness ratings in Study 2. However, the former was significant in only one out of three models, and the latter did not survive statistical correction in the robustness checks. Regarding the overall unclear pattern of hormonal influences, we interpret these findings with caution and suggest that they need to be replicated before being interpreted further. We therefore focus here on the lack of robust, reliable hormonal influences on attractiveness ratings: a) The influence of progesterone and E/P remains unclear, b) estradiol did not reliably affect attractiveness ratings, and c) we found no effects of testosterone or cortisol. Therefore, we could not find evidence for hypotheses that were built on the assumptions of clear hormonal influences on cyclic shifts, e.g. the

“spandrels hypothesis” that women with higher estradiol levels show stronger preferences for masculine men (Havlíček et al., 2015; Shimoda et al., 2018).

There are several possible explanations for our findings. First, we used a variety of methods across both studies (e.g. hormone analyses via LCMS vs. immunoassays) and tested participants from two populations (differing in culture and age spans) in two different labs. This might have induced important differences in the results between the two studies, and compared to previous studies. Second, perhaps hormonal influences are different for voice preferences than for other preferences or sexual desire, which would explain why we did not find the same hormonal influences as those predicting sexual desire (Jones et al., 2018b; Roney & Simmons, 2013; 2016). There is thus a strong need for continued research to clarify the hormonal influences on attraction shifts across the ovulatory cycle. Furthermore, it should be investigated whether hormonal influences on preferences vary across categories of stimuli (e.g. voices, faces, bodies).

No moderating effects of relationship status and perceived stress

In Study 2, we investigated whether women’s relationship status or self-reported stress moderate fertile phase attraction shifts. Whereas prior studies reported that cycle shifts in women’s attraction for men’s bodies or behaviors were found only for partnered women, not for singles (Jünger et al., 2018a; 2018b), we did not replicate this effect for attraction to masculine voices. In line with this, Jones and colleagues (2018b) found no evidence that hormonally driven shifts in women’s general sexual desire were moderated by their relationship status. However, other studies have reported that only partnered women, not singles, showed increased fertile phase sexual desire (Roney & Simmons, 2016) or cycle shifts in preferences for dominant male odor (Havlíček et al., 2005). Thus, the effects of relationship status on psychological changes across the ovulatory cycle remain unclear. Nevertheless, our results clearly fail to support the assumptions of a dual mating strategy (that women may receive fitness benefits when forming a relationship with a reliably investing

man, while seeking good genes from another man through extra-pair sexual encounters; Pillsworth & Haselton, 2006). We also did not find evidence of preference shifts for masculine voices, or a moderating effect of women's relationship status. Moreover, self-reported stress did not moderate fertile phase attraction shifts. Higher stress had a negative effect on sexual and long-term attractiveness ratings, but did not interact with cycle phase. Prior studies reported different evidence: Stress inhibited estradiol levels (Roney & Simmons, 2015) and overrode fertile phase attraction shifts for masculine bodies (Jünger et al., 2018b) and faces (Ditzen et al., 2017) but not for men's behaviors (Jünger et al., 2018a). Hence, stress might affect only the perception of visually available cues in bodies and faces. Self-reported stress values are subjective and might not always reflect physiological stress levels (however, cortisol levels did also not influence attractiveness ratings). To investigate the impact of stress on mate attraction or preferences directly, future studies should manipulate stress experimentally. In sum, future research should investigate under which conditions and for which traits or cues cycle shifts in attraction are influenced by relationship status or self-reported stress. Additionally, other possible moderator variables should be taken into account to gain a better understanding for psychological changes across the ovulatory cycle.

Conclusion

In the current studies, we used substantially larger datasets than those used in prior studies, as well as robust methods of fertility estimation, to investigate possible shifts in women's mate preferences and attraction to male voices across the ovulatory cycle. We found evidence for ovulatory cycle shifts in attraction to men's voices, regardless of masculinity. These shifts were not moderated by women's relationship status or self-reported stress. However, attraction shifts were robust only in Study 2. Although we reported some inconsistent and partly counterintuitive findings for hormonal influences, we robustly showed that there were no preference shifts for masculine voice characteristics. Our results contrast with prior work on preference shifts for masculine voices (Feinberg et al., 2006; Pisanski et

al., 2014; Puts, 2005; see also Puts, 2006), but align with recent reported null replications of cycle shifts for masculine faces, bodies and behaviors (Jones et al., 2018a; Jünger et al., 2018a; 2018b; Marcinkowska et al., 2016; 2018; Muñoz -Reyes et al., 2014). They provide no evidence for the good genes ovulatory shifts hypotheses and suggest that cycle shifts in preferences or attraction are more complex than previously assumed, and that future research is indispensable for clarifying the conditions under which cycle shifts can be found.

Acknowledgements

Study 2 was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – Project number 254142454 / GRK 2070.

For Study 1, we thank Marc Breedlove and Cynthia Jordan for research support, Bradley Alicea, Jill Armington, Emily Barben, Michael Burla, Kathryn Cheney, Michael DiRaimo, Melina Durhal, Rebecca Frysinger, Sana Khan, Mallory Leinenger, Heather Malinowski, Ernestine Mitchell, Joe Morehouse, Charlene Scheld, Kevin Singh, Sara Sutherland, Lisa Vroman, Tyesha Washington, and Molly Zolianbawi for assistance with study preparation and data collection, and Elizabeth Hampson and Bavani Rajakumar for assistance with hormonal assays.

For Study 2, we thank Ruben C. Arslan for valuable statistical advice, Christian Treffenstädt for assistance in the programming process, Kelly Gildersleeve for kindly providing a blueprint of an Excel sheet to calculate fertile windows, Alex Stern for comments on prior versions of this manuscript and our research assistants Laura Botzet, Silvia Bradatsch, Paulina Lauer and Laura Specker-Mattißen, without whom the large data collection would not have been possible.
